Abstract

Compensatory dynamics, during which community composition shifts despite a near-constant total community size, are usually rare: synchronous dynamics prevail in natural communities. This is a puzzle for ecologists, because of the key role of compensation to explain the relation between biodiversity and ecosystem functioning. We take advantage of a long-term wetland bird community time series of 35 years, where we suspected that compensation might occur due to changes in water levels and known trends. We find that compensatory dynamics are still rare, likely due to the synchronizing influence of climate on birds, even after considering several temporal scales of covariation (during cold or warm seasons, above or below the seasonal scale). Negative covariation in abundance at the whole community level did only appear after a management change in the reserve, and at the scale of a few months or several years. Although most research has focused on the temporal scale of compensation vs synchrony, we found that compensation varies with taxonomic and functional scale too: compensation appeared more frequently between rather than within guilds. This suggests that compensation has more potential to emerge between broad functional groups rather between species.

Introduction

Ecological theory suggests that within rich communities, where a number of species can have similar functions due to their proximity in morphological or phylogenetic space, they might exhibit compensatory dynamics (Gonzalez and Loreau, 2009). Compensation occurs when individuals of some species replace individuals of other species, either because of explicit competitive processes or shifts in some environmental driver that change selection pressures. This is particularly likely to occur when there is a space or resource constraint combined with temporal environmental variability. Which species "win" at any particular point in time may then depend on the fine-grained temporal environmental variation, or just on priority effects (i.e., who gets there first). Whatever the cause of compensatory dynamics, its main consequences for ecosystem functioning is that the community as a whole exhibits lower biomass variation than its constituent species (Gross et al., 2013). Compensation is therefore intertwined with community-level stability, at least when stability is understood as the reciprocal of variability. By contrast, another very frequently observed outcome on biodiversity time series is synchrony (Vasseur et al., 2014). Synchrony occurs when all species fluctuate in phase, and therefore the biomass of the community may not fluctuate less than its constituent parts.

Early investigations of the frequency of synchronous vs compensatory dynamics focused on the variance ratio, that is, the variance of the sum of the community biomass divided by the sum of the variance of the component species biomasses (Houlahan et al., 2007; Gonzalez and Loreau, 2009). Unfortunately, this metric is not appropriate for communities subjected to community-wide environmental forcing (Ranta et al., 2008), because a main environmental driver (e.g., temperature or light) may synchronize species abundances or growth rates at some scale, creating large variance in community-wide biomass, in spite of strongly competitive dynamics. Further research has therefore focused on specific timeframes where compensatory dynamics may be found (e.g., below the seasonal scale where temperature fluctuations

44 tend to synchronize species dynamics, Vasseur et al., 2014).

45 Despite this effort to look for more meaningful temporal scales in community-level time
46 series, temporal compensation has remained surprinsingly elusive in the field (Houlahan et al.,
47 2007; Vasseur et al., 2014); but see Ernest et al. (2008); Christensen et al. (2018). Most
48 datasets used so far to evaluate temporal compensation vs synchrony involve planktonic
49 organisms (Vasseur and Gaedke, 2007; Vasseur et al., 2014) or terrestrial plants (Houlahan
50 et al., 2007; Gross et al., 2013; though see Bell et al. 2014). Here, we take advantage of a
51 long-term bird time series record at the monthly scale (over 35 years[1]), in a natural reserve,
52 that allows us to dig deeper into patterns of synchrony, at several temporal and taxonomic
53 or functional scales.

54 Indeed, taxonomic scale should be a main modulator of synchrony/compensation, and this
55 explanatory factor that has been somewhat neglected for now. On the one hand, one could
56 argue that compensation should be higher between closely related species, because functional
57 and phylogenetic differences are generally correlated. For example, if species A and B are
58 two duck species that share almost the same food niche as well as many traits, it makes
59 little difference to the rest of the community whether one species gets replaced by the other
60 (functional compensation, *sensu* Gonzalez and Loreau 2009) so that individuals from species
61 A or B would experience similar competition. Priority effects and chance events could then
62 determine whether duck species A or B dominates. On the other hand, it could be argued
63 that these two similar duck species will precisely respond in similar ways to environmental
64 variables, which tends to obfuscate compensation. Under the latter scenario, more dissimilar
65 species, or groups of species (within the same trophic level nonetheless), could compensate
66 each other within the whole community. This should occur because more dissimilar species
67 are more likely to have different environmental preferences and the environment varies over
68 time (e.g., groups of species preferring more open vs more closed habitats replacing each other

---

[1]Considering only the years used in our analysis. Otherwise, the dataset begins in 1973.

as a function of changes in vegetation height). Surprisingly, such compensation *between* guilds has been less well explored than within guilds, even though there is actually some empirical evidence for compensation between dissimilar guilds (e.g. Sinclair et al., 2013). In this paper, we explore different ways to cluster the bird community, within or between guilds, along either taxonomic or functional classifications.

Our objective is therefore to examine how synchronous or compensatory bird communities are at different temporal and taxonomic (or functional) scales. Our dataset is ideally suited to the task given that (i) it is a highly temporally resolved time series with respect to the species typical generation times, but it also extends well beyond generation time (35 years) and (ii) the reserve where the data has been collected was subjected to a major management change c. 2006 (change in water levels), favoring different types of wetland birds (so that over long timescales, there is a real potential for changes in community composition).

Material and Methods

Data

The monthly time series used for the statistical analyses have been collected at the Teich Ornithological Reserve, Arcachon Bay, France (44.64°N / -1.02°E), by the staff of the Teich reserve. The reserve comprises 120 ha of wetlands, and the counts have been aggregated at the reserve scale. We use for each species the maximum observed abundance over a month, which provides a "monthly snapshot" of the bird abundance. In the statistical analyses, we use both the original monthly data and seasonal averages. We defined two seasons based on observations of bird presence. We defined a 'warm season', from May to August, and a 'cold season' as the months between November and February of the following year. From an ecological viewpoint, this seasonal classification separates wintering birds from summer residents (some of whom are breeding). This makes sense biologically because the two communities

5

have different requirements and respond differentially to abiotic drivers. It is also useful from a more statistical perspective, as there is a shift in composition between the seasons, though winter and summer communities partially overlap due to a number of shared species.

Fig. 1 shows the patterns in abundance for key groups in the Teich reserve bird community, showing the marked signature of seasonality.

Statistical Analyses

We used for yearly analyses the synchrony index η defined by Gross et al. (2013), which is constructed as the mean cross-correlation between each species biomass and the summed biomasses of the rest of the community (eq. 1).

$$\eta = \frac{1}{n} \sum_i \mathrm{Corr}(P_i, \sum_{j \neq i} P_j) \tag{1}$$

where P_i is the abundance or biomass of species i in a community of n species. This synchrony index described in eq. 1 varies between -1 (perfect compensation, total biomass is constant) and 1 (complete synchrony), while 0 represents a case where all populations fluctuate independently. Contrary to other indices (e.g., Loreau and de Mazancourt (2008)'s ϕ), this index is independent from the richness n of the community (or more generally the number of system components) and its overall stability (Hallett et al., 2016). This is particularly important here as we perform analyses at different taxonomic scales, and therefore with a different n in eq. 1.

We computed synchrony indices at the year $\times$ season scale (that is, for a given cold or warm season each year) using the codyn package in R (Hallett et al., 2016). We averaged monthly bird abundances, for each species, over the season duration, and computed the synchrony index using the year as our statistical unit. We also differentiated periods before and after 2006, given that a management change occurred within the reserve in 2006. We

6

considered both the synchrony inside a given group (e.g., among species of the *Anas* genus)
or between groups (e.g., between the summed abundances of the 9 species of genus *Anas*
and the sum of the 12 *Calidris* species). In the latter case of between-groups comparisons,
we summed species together before seasonal averaging, to consider seasonal averages of the
monthly group density.

We used both taxonomic classifications of the species (i.e., between and within genera)
and functional classifications of the species (e.g., 30 species of waders vs 34 species of ducks)
as we suspected that a functional classification may allow to partition better the abiotic
requirements of the species. We use "duck" as a shorthand for the larger functional group of
herbivorous divers, because the birds in that category are mostly ducks: this group includes
nonetheless all anatids (geese and swans in particular) as well as the common coot *(Fulica*
atra, an abundant species here). We also "zoomed in" on a group of species that were known
to exhibit potentially compensatory dynamics (through competition for roosting sites): the
great cormorant *(Phalacrocorax carbo)*, the little egret (*Egretta garzetta*) and the grey heron
(*Ardea cinerea*). The little egret and the grey heron abundances were summed because of
their similar requirements (i.e., they form a small functional group).

We computed statistical significance of synchrony index values using Monte Carlo ran-
domizations (Gouhier and Guichard, 2014). For each set of time series (each combination
year × season), we kept the auto-correlation of the species time series, but removed the cross-
correlation between species by shifting each time series by a random lag (Purves and Law,
2002). We obtained 100 sets of randomized time series for each season and period of time con-
sidered and computed the corresponding synchrony index. We then compared the observed
values of η to the values obtained with the randomized time-series. Independence of species
was rejected at the Bonferroni-corrected 10% threshold. In addition to the time-domain anal-
yses above, we performed frequency-domain analyses, in particular for analyzing synchrony
within the rich wader community, as well as the group formed by the great cormorant, grey

heron and little egret. Based on the work by Keitt (2008) and follow-up by Vasseur et al. (2014), we used the wavelet transform of the time series to measure the coherency between time series

$$\rho(t, s) = \frac{\Lambda_{t,s}(|\sum_k w_k(\tau, s)|)}{\Lambda_{t,s}(\sum_k |w_k(\tau, s)|)} \qquad (2)$$

where $w_k(\tau, s)$ is the continuous Morlet wavelet transform of species k at time τ for scale s, $\Lambda_{t,s}(.) = \int_{-\infty}^{+\infty} e^{-\frac{1}{2}(\frac{t-\tau}{s})^2}(.)d\tau$ and $|.|$ is the modulus of the complex number. The numerator corresponds to the total biomass variation while the denominator corresponds to the variations of each species. This index is close to 0 when species compensate and reaches 1 when they are synchronous. As before, the significance of each value was tested at the 10%, Bonferroni-corrected, threshold by 100 phase-randomizations of each species time series, and computation of the corresponding ρ values.

All datasets and statistical analyses are available in a GitHub repository `https://github.com/fbarraquand/BirdTimeSeries_Teich`[2].

Results

Using a taxonomic classification of the community (focusing on the genera *Calidris* and *Anas* as two key examples of contrasted birds), we can see that within-genus synchrony indices at the seasonal scale are always positive whenever significantly different from the null hypothesis (no temporal correlation between species), i.e. there is no compensation within a genus (Fig. 2). This matches the patterns obtained within the entire wetland bird community (Fig A1 in Appendix 1). For the cold season, *Calidris* and *Anas* exhibit opposite trends in synchrony in response to the management change in 2006. However, for the warm season, the management change, which consisted in lowering the water levels, created more synchronous communities

---

[2]Made public upon acceptance and archived in Zenodo

of species within the *Anas* and *Calidris* genera. This increase in synchrony after 2006 is matched by the functional group classification.

Even though there is no widespread community-wide or genus-wide compensation at the yearly timescale (differentiating the seasons), there could be compensation at finer temporal scales, e.g. a month or two, or coarser scales, over several years. When we consider the wavelet plot (Fig. 3), that is a time-varying and scale-dependent strength of synchrony, we can see that there is synchrony even at a fine temporal scale throughout most of the time series. However, post-2006, there seems to be a possibility for overcompensation on a scale around 5 years or around 3-4 months.

There are therefore relatively contrasted results regarding the effect of the management change on short-term synchrony within the wader community. At the yearly (season) timescale, it seems to increase the synchrony (though the Gross index and wavelets provide slightly different answers). At even shorter timescales though, it seems to decrease it.

More clear-cut results can be found when we examine the synchrony vs compensation between functional groups (Fig. 2d). Since we consider only two functional groups, the Gross index reduces to a simple correlation. Waders and ducks are negatively correlated during the cold season and positively correlated during the warm season. These patterns are in contrast unclear when using a taxonomic classification (no compensation, Fig. 2c).

While compensation could be expected upon visual inspection of the time series of the two groups formed by cormorant on the one hand, and egret plus heron (summed as a small functional group) on the other hand (Fig. 4), we see on Fig. 5 that synchrony is in fact the rule around the annual scale and below, when considering the wavelet index. We wondered if the patterns in Fig. 4 were caused by the use of a log scale, but we found that in fact the correlation was higher rather than lower on the log scale (Appendix 2). However, over long temporal scales ($\sim$ 6 years) there seems to be some compensation, which may indicate a progressive change in composition within this small community module, that was already

9

visible on the time series plot (Fig. 4). There might be some compensation over very short timescale as well (within the season), but at very specific times and the biological mechanisms for this are unclear, since these species compete for roost sites, a process that it unlikely to manifest at such very short timescales.

Discussion

Compensation was overall very rare at the yearly timescale (differentiating between the cold and warm season). At short timescales (below the season), and among taxonomically or functionally close species, some compensation could be found but only at certain periods. In other words, there was no widespread "functional compensation" (*sensu* Gonzalez and Loreau 2009) *within* genera or guilds at the annual scale or below. Yet, summing species abundances within a guild and comparing the "biomass sums" of contrasted guilds, community composition did change in frequency in the long run; in other words, there was some compensation *between* guilds.

Given that we compare the level of synchrony/compensation within guilds (with many species) and between guilds (with only a handful of groups), we checked in Appendix 3 if changing the number of "compartments" (n) in the Gross η index could affect its value: it did not. However, we found that if two groups respond in opposite ways to a shared driver, the stronger the response to the driver, the lesser the compensation indicated by η at the whole community level. This might explain the low levels of compensation that we found at the overall wetland bird community level (Appendix 1), in spite of the clear presence of two groups reacting in opposite way to shared driver (here, water levels). Analyses at several taxonomic/functional scales are therefore warranted to be conclusive about compensation.

We used correlation between the summed abundances of closely related species (species within the *Anas* genus vs species within the *Calidris* genus) or the summed abundances of

10

functionally similar species (waders vs ducks) to uncover compensation. The functional group classification produced much more clearly compensation between guilds than the taxonomic classification. We expected to see compensation at that "functional scale" irrespective of the season, because the requirements of these birds are different, but here waders and ducks were found to correlate negatively only during the cold (wintering) season. This may be because the summer is characterized by a broad inflow of birds, including non-resident individuals that somehow add random variation to the community dynamics (though other explanations are possible).

It may be better to say that we detected "compensation" rather than "compensatory dynamics" between bird species (Gonzalez and Loreau, 2009) as the observed long-term changes in species composition (more waders, proportionally less ducks; Appendix 4) might be due to an increased inflow of birds preferring low water levels, and outflow of birds preferring high water levels, under an overall space constraint. In other words, the shift in community dynamics is likely not directly due to birth and deaths. However, despite the importance of movements and habitat preference to the local community dynamics, there is certainly also an influence of the regional changes in births and deaths on these local dynamics. Zooming in on the cormorant-heron-egret module, we find that compensation mostly occurs above the annual temporal scale, and predominantly in summer as well as before 2006. This occurs because of a slow replacement of species due to competition for resting/roosting sites in the summer season (C. Feigné, pers. obs.), which mostly occurred before 2006.

Overall, our results suggest to search for compensation more often *between* rather than *within* functional groups, and over relatively long timescales above that of the dominant driver (e.g., above 5 years if the main driver is a seasonal climate). This goes against calls to search for compensation at very short timescales (Vasseur and Gaedke, 2007; Gonzalez and Loreau, 2009) in order to filter out the effect of the main seasonal driver. Although searching for compensation at temporal scales below the seasonal abiotic driver (e.g., tem-

11

perature) was partly motivated by studies on plankton whose community dynamics are much faster, we could have expected compensation to manifest also that scale here as well (e.g., monthly). Movement of birds reacting to food availability can certainly occur that fast, and wetlands have a finite carrying capacity, which could promote short-term compensation. We suspect that instead, because many species share common abiotic drivers at short temporal scales (Loreau and de Mazancourt, 2008), compensation is bound to be quite rare below the dominant temporal scale of the environment.

In many ways, searching for compensation using biodiversity time series data is searching for needles in a haystack: only some specific temporal and functional/taxonomic scales allow to see compensation whilst numerous confounding factors make the community co-vary positively at all other scales (Vasseur et al., 2014). Although the knowledge of specific biological mechanisms increasing the densities of some species at the expense of others can help, synchrony will likely dominate community-level time series data for closely related species, even in species that compete strongly (Ranta et al., 2008). This is true even in cases of known mechanisms of competition or shifts in community composition due to abiotic changes as in this study. We suggest that "zooming out" taxonomically or functionally (considering summed abondances of dissimilar functional groups) and temporally (considering temporal scales well above the dominant driver) may often be the best strategy to see the compensation that will inevitably manifest if the community-level abundance is maintained within bounds.
